#### Abstract

Two conversion schemes may be employed for assessing income inequality from household equivalent incomes: to weight household units by size or by needs. Using data from the Luxembourg Income Study, we show the sensitivity of country inequality rankings to conversion schemes and explain the finding by means of inequality decomposition. A bootstrap approach is implemented to test for statistical significance of our results.

Key words: inequality, equivalence scale, equivalent income, weighting, heterogeneous distribution, quasi-homogeneous distribution, inequality decomposition.

JEL-Codes: D31, D63, I32

## 1 Introduction

Researchers and the public are eager to know about the distribution of living standards in a society. Living standard of the household's members is determined by the material comfort derived from available goods and services. Economists consider the income distribution as a close proxy for the distribution of living standard. When heterogeneous household types are involved, two complications emerge. First, different household types have different needs, meaning that members of differently sized/structured households with the same household income may attain different living standards. To obtain a measure that reflects differences in living standards across household types, household incomes must then be adjusted for differences in needs. Second, for reasons concerning possible violations of axiomatic properties of inequality measures, household size heterogeneity also raises the issue of an adequate household weighting when the distribution of living standards is derived. For a rigorous analysis regarding the possibility of such violations of axiomatic principles in inequality measurement, see, for example, Ebert and Moyes (2003).

A broad consensus exists concerning the differences-in-needs adjustment procedure. Usually, household incomes are deflated by so-called equivalence scales (see, for a thorough discussion, Schröder 2009). Equivalence scales are measures of intra-household sharing potential and differences in family members' needs (i.e., of adults vs. children). Normalizing the equivalence scale of a childless one-adult household (the reference type) to a value of one, an equivalence scale gives the percentage change in household income required to maintain the household's living standard as household members are added. Accordingly, equivalence scales measure household-size economies. Dividing household income by equivalence scale gives the needs-adjusted equivalent income of the household.

Concerning the household-weighting procedure, the traditional approach in inequality measurement is a weighting of households by household size. ${ }^{1}$ As an example, when the Theil index is derived from a distribution of needs-adjusted equivalent incomes, a one-member household is weighted by one and a four-member household by four. Size weighting accommodates the principle of normative individualism: any person is considered as important as any other and is assigned the same weight. Therefore, the size-weighted equivalent-income distribution depicts differences in living standards among individuals.

[^0]Although size weighting seems straightforward and intuitive, there is a lively debate going on. One argues about its foundation in the context of inequality, poverty, redistribution and horizontal equity analyses (see, for example, Vickrey 1947, Bruno and Habib 1976, Pyatt 1990, Bottiroli Civardi and Martinetti Chiappero 1995, Cowell 2000, and Lambert 2004). Particularly, some authors advocate a weighting of households by needs, i.e. by households' equivalence scales. ${ }^{2}$ The so derived needs-weighted equivalent-income distribution depicts differences in living standards of equivalent adults. The specific characteristic of a needs weighted distribution is that income transfers between households leave the aggregate equivalent income unaltered. This property is violated if units are size-weighted and income transfers involve heterogeneous household types. Consider the following household income distributions:

| Income | Number of <br> household <br> members | Equivalence <br> scale |
| :---: | :---: | :---: |
| 1 | 1 | 1 |
| 3 | 3 | 2 |

In this example, total equivalent income amounts to $1 \cdot(1 / 1)+(3 / 2) \cdot 2=4$ in case of needs weighting, as opposed to $1 \cdot(1 / 1)+(3 / 2) \cdot 3=5.5$ when households are weighted by size. Now, let there be a transfer of 0.3 income units from the three-member to the one-member household. The transfer leaves total equivalent income unaffected when households needs are weighted: $1 \cdot(1.3 / 1)+(2.7 / 2) \cdot 2=4$. On the contrary, size weighting indicates a reduction in total equivalent income: $1 \cdot(1.3 / 1)+(2.7 / 2) \cdot 3=5.4$ as opposed to 5.5 before the transfer. The reduction in total equivalent income results from the fact that the one-member household has no economies of household size and is thus a rather inefficient vehicle for converting income into equivalent income units. ${ }^{3}$ Characterizations of size and needs weighted distributions can be found in the theoretical works of Ebert (1999, 2004), Ebert and Moyes (2003), and Shorrocks (2004).

As outlined above, axiomatic works have explored the impact of needs vs. size weighting on distributional measures, yet the quantitative effects on actual income is still unknown. The present work provides for the first time a systematic sensitivity analysis of cross-country

[^1]inequality rankings to weighting schemes. Moreover, we provide a framework to isolate the channels that make needs- and size-weighting distributions and derived inequality measures and country rankings different.
More precisely, the problem we are concerned with is the role of weighting schemes in ranking personal-income inequality across countries. Our first contribution is to provide a systematic sensitivity analysis of country inequality rankings to weighting schemes. In particular, we want to answer questions of the following type: "For a given inequality index and equivalence scale, do positions of the United States and France in inequality rankings differ when households are weighted by needs rather than size?" The sensitivity of country rankings to weighting procedure is scrutinized for different inequality indices at all admissible of household-size economies. Rankings are derived from a set of 20 countries from the Luxembourg Income Study, and bootstrapping techniques are applied to testing for significance of the results.

Indeed, country inequality rankings turn out to be sensitive to the choice of weighting schemes. Apart from very low levels of household-size economies, Kendall's tau is always significantly different from 1, indicating that the correlation of size and needs weighted country inequality rankings is not perfect. Moreover, the correlation tends to become weaker with the presumed level of household size economies.
Our second contribution is the identification of the mechanics underlying the differences in rankings obtained from size and needs weighted distributions. An inequality decomposition by household types serves as the technical workhorse. The decomposition expresses overall inequality as the sum of inequality within and between population subgroups (household types). Both the within-group and the between-group component are sensitive to weighting schemes. We show that the quantitative effect hinges on the interplay of household-type specific inequality levels (and differences in the levels across household types), householdtype specific mean incomes, and the relative frequencies of households of specific types. All these factors are country-specific. Consequently, switching from one weighting scheme to another may well affect measured inequality differently in one country compared to another, with implications for the positions of the countries in inequality rankings.

Here is a roadmap to our paper. Section 2 gives a brief introduction into the equivalence scale literature, hereby focusing on the technical challenges regarding the identification of equivalence scales. Section 3 introduces the database. Section 4 introduces the applied inequality indices, the bootstrap method, and the inequality decomposition by population subgroups. Section 5 summarizes our findings concerning the sensitivity of country rankings
to weighting procedure. Section 6 explores the underlying mechanisms by means of inequality decomposition. Section 7 concludes the paper.

## 2 Equivalence scales

When households differ in size and needs, a needs adjustment of incomes (or expenditures) is necessary to yield comparable figures in terms of material living standard. Equivalence scales are assessed as an adequate instrument of adjustment. Yet, little consensus exists regarding the appropriate strategy of identification of equivalence scale and thus the 'true' equivalence scale. Again, the choice of the equivalence scale is not innocuous for distributional measures (see, for example, Aaberge and Melby 1998, Coulter et al. 1992, and many follow-up studies). In the following, we give a brief introduction into the literature on equivalence scales, hereby focusing on the general ideas and related technical difficulties, and motivate the choice of the equivalence scale applied in the current study. Hereby, we closely follow Schröder (2009).

Basically, two streams of research on the estimation of equivalence scales can be distinguished, each having particular weaknesses and strength. The econometric approach derives equivalence scales indirectly form revealed-preference data (household expenditure and time-use data); another approach relies on stated-preferences from surveys and quantifies equivalence scales directly.

The indirect econometric approach is based on models of household behavior. Since Engel's pioneering work (1857, 1895), a vast literature has emerged that aims for uncovering equivalence scales from family expenditure (and sometimes time-use data), relying on the axiom of revealed preference. Essentially, this means that a family's preferences can be revealed by its demand patterns, and equivalence scales can be uncovered through estimates of household cost functions. Various factors make the indirect approach challenging. Particularly, the information ${ }^{4}$ that is required for an assumption-free estimation is not available in existing data bases (Browning 1992: 1470). As a result, estimates of equivalence scales depend critically upon assumptions of exogeneity, within-household sharing, and household production techniques.

The central idea of the econometric approaches is the quantification of equivalence scales through household cost functions built on estimates of consumer demand systems. ${ }^{5}$ The equivalence scale of household type $h$ relative to type $r$ is $E S_{r}^{h}=C\left(p, u, z^{h}\right) / C\left(p, u, z^{r}\right)$,

[^2]where $C=C(p, u, z)$ is the household cost function, i.e. the minimum expenditures required for a household with socio-demographics characteristics $z$ to attain utility level $u$ given a price vector $p$. The cost function $C(p, u, z)$ is 'conditional' (see Pollak 1989) on the family having the characteristics $z$.
Persuasive as the econometric approach sounds, it is challenged by the fact that household utility cannot be observed directly. Accordingly, household cost and Hicksian demands are unobservable as well. Instead, only Marshallian demands can be observed. The crucial complication is that Marshallian demands derived from $C(p, u, z)$ and $C(p, \rho(u, z), z)$ are identical for any function $\rho(u, z)$ which is strictly monotonically increasing in household utility, together with the fact that the derivation of equivalence scales requires welfare comparisons involving different household types. Demand data, however, only reveal the shape and ranking of indifference curves, but not the associated utility levels. This is the socalled under-identification problem.

If no further information is available, to assess equivalence scales additional assumptions on the $\rho-z$ nexus are required. Maybe the most well-known identification assumption is the 'independence of base’ (Lewbel 1989) or 'equivalence scale exactness’ assumption (Blackorby and Donaldson 1993). It assumes cost functions across family types to be proportional with respect to reference income, giving equivalence scales which are, by definition, independent from income. More general functional forms for identification have been suggested by Donaldson and Pendakur (2004, 2006), allowing equivalence scales to be income dependent. Further, identification issues (simultaneity of demand and supply equations, estimation of equivalence scales without price variation, interpersonal comparability, ordinality and cardinality of household utilities) are summarized in Lewbel (1997) and Slesnick (1998). Another question relates to the way family demographics are modeled in Marshallian demand functions (for further details see Lewbel 1997: 185ff.).

In sum, despite all advances being made since the early studies of Engel, one crucial problem remains: the (general) equivalence scale cannot be derived from demand data alone without further assumptions (see Muellbauer 1980). It may be for this reason that survey approaches have been suggested which attempt to derive equivalence scales directly from peoples' assessments concerning the relationship between income, household type and economic wellbeing.

The central idea behind the survey approach is that, every day, people make decisions considering intra-household sharing potentials and differences in needs, and, hence, should be experienced enough to assess equivalence scales. Since the pioneering works by van Praag
(1971) and Kapteyn and van Praag (1976), survey approaches have been implemented by several authors including Colasanto et al. (1984), Danziger et al. (1984), Ferrer-i-Carbonell (2005), and Koulovatianos et al. (2005, 2009). ${ }^{6}$

For the survey approach to be effective, it must be ensured that respondents understand the survey questions sufficiently well, so that responses are not biased as a result of cognitive problems. However, several response phenomena potentially limit the information content of survey data. ${ }^{7}$ Moreover, measuring in terms of 'well-being' can make estimates sensitive to minor life events (see, for example, Schwarz and Strack 1999: 62). ${ }^{8}$

Maybe for the weaknesses of the direct and indirect approaches, institutions have suggested or apply 'rules of thumb' equivalence scales, relying on the assessments of experts. Examples include the OECD modified equivalence scale, the square root scale and its generalization, the Buhmann et al. (1988) scale, $\operatorname{ES}\left(n_{i}, \theta\right)=\left(n_{i}\right)^{\theta}$, where $n_{i}$ denotes the number of household members living in household unit $i$, and $0 \leq \theta \leq 1$ is the 'equivalence-scale elasticity'. Although more elaborate equivalence scales exist, we have chosen the Buhmann et al. equivalence scale in the empirical part of the paper for three reasons. First, it is simple but flexible enough to systematically scrutinize the sensitivity of country rankings to the supposed level of household-size economies, as captured by $\theta$. This is particularly useful for our purposes as needs and size weighting are equivalent procedures when $\theta$ is one. Second, the scale is independent of base, and thus fits in the axiomatic framework of Ebert and Moyes (2003) that motivated our empirical analysis. One key result of Ebert and Moyes (2003) is that 'reference independence' is violated once income-dependent equivalence scales are considered. Reference independence requires that "other things equal, the ranking of situations does not depend on the particular chosen reference type" (Ebert and Moyes 2003: 328). ${ }^{9}$

## 3 Database and data preparation

Our empirical examination is based on Luxembourg Income Study (LIS) data. For 30 countries and several years, the LIS provides representative micro-level information on

[^3]private households’ incomes and demographic characteristics (e.g., number, age and gender of each family member). To keep the empirical analysis tractable, we consider 20 countries (the United States and 19 European countries) from a single cross section. ${ }^{10}$ Additionally, the analysis is restricted to data from nine household types: one- and two-adult households with zero up to three children, and childless three-adult households. ${ }^{11}$ Tables A1 and A2 in the Appendix provide the country codes and several non-weighted country-specific characteristics. ${ }^{12}$

Our computations rely on the LIS variable 'household disposable income’. Household disposable income is harmonized across countries, covers labor earnings, property income, and government transfers in cash minus income and payroll taxes. ${ }^{13}$ It is denoted in local currencies. We have removed household observations with missing information or with negative values of disposable income. Moreover, to avoid outlier-driven biases of inequality estimates, we have trimmed the data following standard conventions: the one percent observations with the highest and with the lowest incomes have been discarded.

As mentioned in Section 2, we apply the parametric equivalence scale suggested in Buhmann et al. (1988), $\operatorname{ES}\left(n_{i}, \theta\right)=\left(n_{i}\right)^{\theta}$, where $n_{i}$ denotes the number of household members living in household unit $i$ to derive equivalent income from household disposable income. Accordingly, equivalent income is $y_{i}\left(y_{i}^{d}, n_{i}, \theta\right)=y_{i}^{d} / E S\left(n_{i}, \theta\right)$ where $y_{i}^{d}$ denotes household $i$ 's disposable income.

In the empirical examination, country rankings will be provided for the whole range of household-size economies, i.e. for any level of $\theta$ from zero to one. Concerning the level of household size economies, two extreme cases can be considered. If $\theta=0$, equivalent income and disposable income are the same for all household types since $E S\left(n_{i}, 0\right)=1 \forall i$. Due to perfect household-size economies, ' $n$ household members live as cheap as one' and the same weight - irrespective of household size - is assigned to all household units in the needs weighted distribution. If $\theta=1$, household-size economies cannot be achieved and 'one $n$ member household lives as cheap as $n$ one-member households.' In this special case, size and needs weighting assign identical household weights as $E S\left(n_{i}, 1\right)=n_{i} \forall i$.

[^4]
## 4 Measurement concepts

### 4.1 Inequality indices, country rankings and rank correlation

We measure inequality with indices from the generalized entropy class, $G E(a)$, derived from the analogy between income distribution and information theory. The parameter $a$ determines the sensitivity of $G E(a)$ with respect to changes at the top of the income distribution. The larger is $a$, the more sensitive is $G E(a)$. For $a=0$ we have the mean logarithmic deviation; for $a=1$, we have the Theil coefficient; and for $a=2$ we have half the square of the coefficient of variation.

Consider a population of $i=1, \ldots, I$ households with equivalent incomes $y_{i}\left(y_{i}^{d}, n_{i}, \theta\right)$. Each observation $i$ is assigned a weight $w_{i}^{t}$ with $t \in\{S, N\}$, where $S$ denotes size and $N$ needs weighting. In case of $S$-weighting, a household's weight is $w_{i}^{S}=n_{i} \cdot f_{i} /\left(\sum_{i=1}^{I} n_{i} \cdot f_{i}\right)$, with $f_{i}$ denoting the LIS frequency weight. In case of $N$-weighting, the weight is $w_{i}^{N}=E S\left(n_{i}, \theta\right) \cdot f_{i} /\left(\sum_{i=1}^{I} E S\left(n_{i}, \theta\right) \cdot f_{i}\right)$. The Generalized Entropy class of inequality indices is given by

$$
\begin{align*}
& G E(a ; t, \theta)=\frac{1}{a \cdot(a-1)} \cdot\left[\sum_{i=1}^{I} w_{i}^{t} \cdot\left(\left(\frac{y_{i}\left(y_{i}^{d}, n_{i}, \theta\right)}{\mu(t, \theta)}\right)^{a}-1\right)\right], a \neq 0,1  \tag{1a}\\
& G E(1 ; t, \theta)=\sum_{i=1}^{I} w_{i}^{t} \cdot \frac{y_{i}\left(y_{i}^{d}, n_{i}, \theta\right)}{\mu(t, \theta)} \cdot \log \left(\frac{y_{i}\left(y_{i}^{d}, n_{i}, \theta\right)}{\mu(t, \theta)}\right)  \tag{1b}\\
& G E(0 ; t, \theta)=\sum_{i=1}^{I} w_{i}^{t} \cdot \log \left(\frac{\mu(t, \theta)}{y_{i}\left(y_{i}^{d}, n_{i}, \theta\right)}\right) \tag{1c}
\end{align*}
$$

where $\mu(t, \theta)=\left(\sum_{i=1}^{I} y_{i} \cdot w_{i}^{t}\right) / \sum_{i=1}^{I} w_{i}^{t}$ denotes mean equivalent income - per individual in case of size weighting and per equivalent adult in case of needs weighting.
Ordering all the countries in decreasing order of $G E(a ; t, \theta)$ gives the country inequality ranking for a specific $a$, a specific weighting procedure $t$ and a specific level household-size economies $\theta$. With $r^{l}(a ; t, \theta)$ we denote the rank of country $l=1, \ldots, L$. For a given $a$ and $\theta$ , we assess the strength of the relationship between the $S$ - and $N$-weighted country
inequality ranking by means of Kendall's tau, $\tau$. Kendall's tau, like the Spearman rank correlation, is carried out on the ranks of data. Particularly, it is determined by the probability of observing concordant and discordant rank-pairs.
For pairs of ranks $\left(r^{l}(a ; S, \theta), r^{l}(a ; N, \theta)\right)$ and $\left(r^{m}(a ; S, \theta), r^{m}(a ; N, \theta)\right)$ of countries $l \neq m$ define them as concordant if $\left(r^{l}(a ; S, \theta)-r^{m}(a ; S, \theta)\right) \cdot\left(r^{l}(a ; N, \theta)-r^{m}(a ; N, \theta)\right)>0$, and discordant if the product is negative. ${ }^{14}$ Let $P(a ; \theta)$ and $Q(a ; \theta)$ denote the number of concordant respectively discordant pairs, then

$$
\begin{equation*}
\tau(a ; \theta)=\frac{P(a ; t, \theta)-Q(a ; t, \theta)}{L \cdot(L-1) / 2} \tag{2}
\end{equation*}
$$

Kendall's tau takes values between -1 and +1 , with a positive (negative) value indicating that ranks obtained from $S$ - and $N$-weighted distributions are positively (negatively) correlated. For $\tau=1$, the positive correlation is perfect, i.e. $S$ - and $N$-weighted ranks of all countries coincide.

### 4.2 Inequality decomposition

To understand the mechanics underlying the differences in size and needs weighted country inequality rankings, i.e. $\tau \neq 1$, we conduct an inequality decomposition by household types. Suppose there is an exhaustive partition of the population into mutually-exclusive subgroups $k=1, \ldots, K$. The basic idea is to express overall inequality as a function of inequality within and between population subgroups. We partition the population into nine subgroups, distinguished by household composition.
Decomposability of an inequality index implies a coherent relationship between inequality in the whole population and inequality in its constituent mutually exclusive subgroups. An index is additively decomposable if it can be written as a weighted sum of the within-subgroup inequality indices plus a between-subgroup term based on mean equivalent incomes and subgroup sizes. Indices of the generalized-entropy family are additively decomposable and can be written as

$$
\begin{equation*}
G E(a ; t, \theta)=G E W(a ; t, \theta)+G E B(a ; t, \theta) \tag{3}
\end{equation*}
$$

[^5]where $G E W$ is within-group inequality, and $G E B$ is between-group inequality. Within-group inequality is defined as
\[

$$
\begin{align*}
& G E W(a ; t, \theta)=\sum_{k=1}^{K} q_{k}^{t} \cdot\left(\frac{\mu_{k}^{t}}{\mu^{t}}\right)^{a} \cdot G E_{k}(a), \quad a \neq 0,1  \tag{4a}\\
& G E W(1 ; t, \theta)=\sum_{k=1}^{K} q_{k}^{t} \cdot \frac{\mu_{k}^{t}}{\mu^{t}} \cdot G E_{k}(1)  \tag{4b}\\
& G E W(0 ; t, \theta)=\sum_{k=1}^{K} q_{k}^{t} \cdot G E_{k}(0) . \tag{4c}
\end{align*}
$$
\]

The expression $q_{k}^{t}$ in equations (4a) to (4c) denotes the population share living in household type $k$. Depending on the chosen weighting procedure, the population share of type- $k$ households equals

$$
\begin{align*}
& q_{k}^{S}=\frac{\sum_{i_{k}=1}^{I_{K}} w_{i_{k}}^{S}}{\sum_{k=1}^{K} \sum_{i_{k}=1}^{I_{K}} w_{i_{k}}^{S}}  \tag{5a}\\
& q_{k}^{N}(\theta)=\frac{\sum_{i_{k}=1}^{I_{K}} w_{i_{k}}^{N}(\theta)}{\sum_{k=1}^{K} \sum_{i_{k}=1}^{I_{K}} w_{i_{k}}^{N}(\theta)}, \tag{5b}
\end{align*}
$$

where $I_{k}$ denotes the (non-weighted) number of household observations of type $k . S$ weighted population shares are constant and do not depend on household-size economies $\theta$. On the opposite, $N$-weighted population shares are dependent on $\theta$ : The higher is $\theta$, the lower is the population share of the larger households relative to the smaller.

The expression $\mu_{k}^{t} / \mu^{t}$ in (4a) and (4b) is the ratio of average equivalent income of type $k$ households relative to the population-wide mean with

$$
\begin{align*}
& \mu_{k}^{S}=\mu_{k}^{N}=\frac{\sum_{i_{k}=1}^{I_{K}} f_{i_{k}} \cdot y_{i_{k}}\left(y_{i_{k}}^{d}, n_{i_{k}}, \theta\right)}{\sum_{i_{k}=1}^{I_{K}} f_{i_{k}}}  \tag{6a}\\
& \mu^{t}=\sum_{k=1}^{K} q_{k}^{t} \cdot \mu_{k}^{t} . \tag{6b}
\end{align*}
$$

Average equivalent income of type $k$ households is the same for both weighting schemes, whereas average equivalent income across households depends on the weighting scheme via the population shares.
The last expression in (4a) to (4c), $G E_{k}(a)$, describes inequality in subgroup $k$. It is calculated as if the subgroup $k$ were a separate population. Due to the fact that all households of a particular subgroup are homogeneous with respect to size, $G E_{k}(a)$ is the same for both types of weighting.
The between-group inequality component, $G E B$, is defined as

$$
\begin{align*}
& \operatorname{GEB}(a ; t, \theta)=\frac{1}{a \cdot(a-1)} \cdot\left[\sum_{k=1}^{K} q_{k}^{t} \cdot\left(\left(\frac{\mu_{k}}{\mu^{t}}\right)^{a}-1\right)\right], a \neq 0,1  \tag{7a}\\
& G E B(1 ; t, \theta)=\sum_{k=1}^{K} q_{k}^{t} \cdot\left(\frac{\mu_{k}}{\mu^{t}}\right) \cdot \ln \left(\frac{\mu_{k}}{\mu^{t}}\right)  \tag{7b}\\
& G E B(0 ; t, \theta)=\sum_{k=1}^{K} q_{k}^{t} \cdot \ln \left(\frac{\mu^{t}}{\mu_{k}}\right) . \tag{7c}
\end{align*}
$$

The between-group inequality from the size weighted distribution differs from the needs weighted as a result of differences in weighted average equivalent incomes, $\mu^{S}$ and $\mu^{N}$, and household type-specific population weights $q_{k}^{t}$. In the empirical part of the paper, the results from the decomposition will serve as a vehicle for explaining the sensitivity of bilateral country inequality rankings to weighting procedure.

### 4.3 Bootstrap inference

To test the statistical significance of our results, we have implemented a bootstrap approach following the theoretical framework outlined in Biewen (2002). In a first step, we create a pooled database from the selected set of 20 countries. From the pooled database, we draw with replacement, $B=100$ random bootstrap samples, using countries as strata. ${ }^{15}$ For each country, each bootstrap sample has as many sampling units as the country-specific LIS database, and each sampling unit has the same probability of being selected. ${ }^{16}$

[^6]Particularly, for each country we compute from each bootstrap sample $b$ a particular measure, $M^{b}$, say the Theil index. Confidence intervals are computed following Hall (1994). Hall's confidence interval at the 95 percent level is defined as $\operatorname{Pr}\left(2 \hat{M}^{c}-M_{0.975}^{b} \leq M \leq 2 \hat{M}^{c}-\hat{M}_{0.025}^{b}\right)=(100-2 \alpha) / 100$, where $\hat{M}^{c}$ denotes the bootstrap bias corrected statistic, $M_{0.975}^{b}$ and $M_{0.025}^{b}$ the $2.5^{\text {th }}$ upper and lower percentile in the bootstrap index distribution, and $M$ the index's true value. The bootstrap bias-corrected index is $\hat{M}^{c}=\hat{M}$ - Bias, where $\hat{M}$ is the index derived from the sampling distribution and Bias $=\frac{1}{B} \cdot \sum_{b=1}^{B} M^{b}-\hat{M}$. The bias-corrected confidence interval has advantages compared to standard confidence intervals when the underlying distribution, as it is the case for income distributions, is skewed (Hall 1994).

To investigate whether the bilateral ranking of any two countries $l$ and $m$ is significantly affected by the weighting procedure, we rely on the confidence intervals' upper and lower limits. The weighting procedure has a significant effect on the bilateral ranking if

$$
\begin{equation*}
\left[\left(2 \hat{M}^{c}-M_{0.975}^{b}\right)_{m}^{s}-\left(2 \hat{M}^{c}-M_{0.025}^{b}\right)_{l}\right] \cdot\left[\left(2 \hat{M}^{c}-M_{0.975}^{b}\right)_{m}^{N}-\left(2 \hat{M}^{c}-M_{0.025}^{b}\right)_{l}^{N}\right]<0 \tag{8a}
\end{equation*}
$$

and/or if

$$
\begin{equation*}
\left[\left(2 \hat{M}^{c}-M_{0.025}^{b}\right)_{m}^{S}-\left(2 \hat{M}^{c}-M_{0.975}^{b}\right)_{l}^{S}\right] \cdot\left[\left(2 \hat{M}^{c}-M_{0.025}^{b}\right)_{m}^{N}-\left(2 \hat{M}^{c}-M_{0.975}^{b}\right)_{l}^{N}\right]<0 . \tag{8b}
\end{equation*}
$$

For example, let the confidence interval for a given measure $M$ and significance level be $[0.20 ; 0.30]_{l}^{S}$ and $[0.26 ; 0.34]_{l}^{N}$ for country $l$, respectively $[0.35 ; 0.40]_{m}^{S}$ and $[0.31 ; 0.37]_{m}^{N}$ for $m$. From (8a) and (8b), we obtain $(0.40-0.20) \cdot(0.37-0.26)>0$, and $(0.35-0.30) \cdot(0.31-0.34)<0$. As (8b) is negative, weighting has a significant effect on the bilateral ranking. More precisely, the size-weighted distribution in $m$ is more unequal than in $l$, while needs weighted distributions statistically exhibit the same level of inequality (confidence intervals overlap).

Taking a broader multinational perspective, we also take inequality indices to draw conclusions concerning the differences in size- and needs weighted cross-country rankings. More precisely, the procedure outlined in (8a) and (8b) is carried out on any pair of countries.

If condition (8a) or (8b) is satisfied (both are rejected), a re-ranking occurs and the respective pair of countries is denoted discordant (concordant). Having identified the number of concordant pairs, $P(a ; \theta)$, and discordant pairs $Q(a ; \theta)$, Kendell's tau, $\tau(a ; \theta)$ is derived from (2).

## 5 Sensitivity of country inequality rankings to weighting schemes

The sensitivity of country inequality rankings to weighting schemes is scrutinized from a bilateral and a multinational perspective. The bilateral perspective is concerned with the question whether two countries $l$ and $m$ are consistently ranked according to the criteria defined in equations (8a) and (8b) or not. The multinational perspective is concerned with the correlation of size and needs weighted cross-country inequality rankings as indicated by Kendall's tau. Both types of sensitivity analysis are carried out for all three entropy inequality indices. For expositional reasons, the presentation focuses at two levels of the equivalencescale elasticity, $\theta=0.5$ and $\theta=0.25$. For $\theta=0.5$, we have the 'square-root scale' extensively used in empirical inequality analyses. The square-root scale is recommended by the Luxembourg Income Study ${ }^{17}$ and is similar to the OECD modified equivalence scale. The latter "assigns a value of 1 to the household head, of 0.5 to each additional adult member and of 0.3 to each child" (see OECD web page on equivalence scales ${ }^{18}$ for details). A householdsize elasticity of 0.25 indicates substantial household-size economies. For the interested reader, Figures 1-2c, provide inequality statistics for all countries and for the whole range of $\theta$.

For our set of twenty countries, Table 1a and Table 1b provide the three inequality indices (point estimates) together with the respective bootstrap confidence intervals underneath. Statistics in Table 1a relate to the $\theta=0.5$ and in Table 1b to the $\theta=0.25$ scenario. The first number in each cell is the observed inequality index in percent. Take Poland (PL) and Slovenia (SI) when $\theta=0.25$ as an example. Point estimates of mean logarithmic deviations, $G E(0)$, from size-weighted distributions indicate more inequality in Poland compared to Slovenia, i.e. 11.45 percent versus 11.38 percent. Overlapping confidence intervals, however, indicate that the difference is insignificant. The needs weighted distributions lead to a different conclusion, i.e. significantly more inequality in Slovenia compared with Poland.

[^7]Table 1a. Size and needs weighted inequality estimates; equivalence-scale elasticity of 0.5

Note. S indicates size weighting, N needs weighting. GE(0) is mean logarithmic deviation; GE(1) is Theil index; GE(2) is half the square of the coefficient of variation. Point estimates and, in parentheses and italics, 95 percent bootstrap confidence intervals. All indices multiplied with 100. See Table A1 in the Appendix for definition of country codes. Own calculations based on LIS 2000 data.

Note. S indicates size weighting, N needs weighting. GE(0) is mean logarithmic deviation; GE(1) is Theil index; GE(2) is half the square of the coefficient of variation. Point estimates and, in parentheses and italics, 95 percent bootstrap confidence intervals. All indices multiplied with 100 . See Table A1 in the Appendix for definition of country codes. Own calculations based on LIS 2000 data.

Tables 2 a and 2 b summarize all inconsistent bilateral rankings from the two types of weighting. Table 2a refers to the $\theta=0.5$ scenario, while Table 2 b refers to $\theta=0.25$. For each pair of countries, "." indicates that bilateral rankings are immune to weighting for all three indices; else a three digit numerical sequence is provided. The first digit relates to a country ranking by means of the logarithmic deviation; the second to a ranking by the Theil coefficient, and the third to the half the square of the coefficient of variation. In the sequence,
a " 1 " (" 0 ") indicates, accordingly to the criteria (8a) and (8b), that bilateral rankings from size and needs weighted distributions are inconsistent (consistent).

For example, take the sequence " 011 " for Germany and Austria when $\theta=0.5$. According to $G E(0)$, both types of weighting lead to the same conclusion, namely that there is significantly more inequality in Germany compared to Austria. According to $G E(1)$ and $G E(2)$, however, conclusions are weighting dependent. While size weighting suggests no significant difference in inequality levels in Germany and Austria, estimates from the needs weighted distributions indicate significantly more inequality in Germany.
We find a non trivial number of inconsistencies in bilateral rankings derived from size and needs weighted distributions. If we consider all the pair-wise comparisons of the 20 countries for $\theta=0.5$, then we have six discordant pairs in case of the logarithmic deviation, nine in case of the Theil index, and five in case of half the square of the coefficient of variation. Accordingly, 3.51 percent of the comparisons yield conflicting rankings. For $\theta=0.25$ the number of discordant pairs more than doubles. Now we have 51 discordant pairs. Correspondingly, 8.95 percent of all the bilateral rankings are sensitive to the weighting procedure. Yet, not only has the mere number of discordances risen, but it is also interesting to note that some bilateral comparisons are sensitive to weighting when $\theta=0.5$ while this is not the case when $\theta=0.25$. Examples include Austria and Germany as well as France and Luxembourg.

Table 3. Kendall's tau and number of discordant pairs

|  | $\theta=0.50$ |  |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: |
|  | GE(0) | GE(1) | GE(2) | GE(0) | GE(1) | GE(2) |
| Kendall‘s $\tau$ (bootstrapped) | 93.68 | 90.53 | 94.74 | 81.05 | 83.16 | 81.05 |
| Kendall‘s $\tau$ (point estimate) | 94.74 | 94.74 | 94.74 | 90.53 | 91.58 | 92.63 |
| Significantly discordant pairs | 6 | 9 | 5 | 18 | 16 | 18 |
| (bootstrapped) | 6 |  |  |  |  |  |

Note. GE(0) is mean logarithmic deviation; GE(1) is Theil index; GE(2) is half the square of the coefficient of variation. $\theta$ denotes the equivalence-scale elasticity. Kendall's tau multiplied with 100. Own calculations based on LIS 2000 data.

The bilateral comparisons clearly indicate discrepancies that arise when switching from one weighting scheme to another. Indeed, various point estimates suggest outright reversals of country ranks when switching from one weighting scheme to another. As example consider point estimates for $G E(0)$ at $\theta=0.5$ from Table 1a. Outright reversals concern Belgium and Slovenia, France and Poland, Finland and Norway, Germany and Poland, as well as Ireland and Italy. At $\theta=0.25$ (Table 1b) outright reversals concern the bilateral positions of Austria and Norway, France and Slovenia, France and Sweden, Finland and Luxembourg, Ireland and United Kingdom, Norway and Switzerland, Poland and Slovenia, as well as Poland and

Sweden. Confidence intervals do not support the presence of outright reversals. Rather they indicate significant differences in inequality levels for one weighting scheme and insignificant differences for the other.

Figure 1. Kendall's tau

Note. Kendall's tau rank correlations of country rankings derived from size- and needs weighted distributions. Black solid line refers to mean logarithmic deviation; black dashed line to Theil index; grey solid line to half the square of the coefficient of variation Own calculations based on LIS 2000 data.

Next we turn to the multinational perspective. Numbers of discordant pairs (significant) together with rank correlation coefficients (point estimates and bootstrapped values) are provided in Table 3. As mentioned above, Kendall's tau gives the correlation of size and needs weighted cross-country inequality rankings. For all three entropy indices, the number of discordant pairs and Kendall's tau indicate a strong correlation of country inequality rankings derived from size and needs weighted distributions. At the same time, the correlation is weaker when household size economies are high (when $\theta$ is small). This impression is reconfirmed by Figure 1. In the graph, three lines are provided. Each line connects Kendall's rank correlation coefficients derived for different levels of household-size economies when countries are ranked according to a particular entropy index. ${ }^{19}$ Take, for example Kendall's rank correlation coefficient derived from Theil index based country rankings. We have a

[^8]correlation of 1.0 for $\theta \geq 0.95,0.989$ for $\theta=0.75,0.947$ for $\theta=0.5,0.916$ for $\theta=0.25$, and 0.895 for $\theta=0.00$.

The shapes of the lines indicate that the relationship between $\tau$ and $\theta$ is not monotonous. This non- monotonicity is consistent with the results from the bilateral comparisons: It is not ruled out that ranks of countries are sensitive to weighting when $\theta$ is high and insensitive when $\theta$ is low.

We want to point out that the sensitivity of country rankings is not a phenomenon restricted to the generalized entropy class of inequality indices. We have also experimented with several other popular measures such as the Gini and the Atkinson index. The results are congruent with abovementioned conclusions. ${ }^{20}$

## 6 Decomposition analysis

This section starts with a general overview of the country-specific estimates from the inequality decomposition for both weighting schemes. Afterwards, we proceed with a detailed two-country case study. It seeks to carve out the country specifics of distributions of income and household types leading to weighting-dependent country rankings.
For admissible values of household-size economies, Figures 2a-2c provide the size and needs weighted levels of inequality, inequality within and inequality between for our three inequality indices. Grey lines refer to size weighting, black lines to needs weighting. Long dashed lines depict the inequality between component, short dashed lines the inequality within component, and solid lines refer to the sum of both, i.e. to the overall inequality index. Figures 2a-2c depict how variations of three ingredients - the functional form of the index (via variation of $a$ ), household-size economies (via variation of $\theta$ ) and the type of weighting (by size versus needs) - affect the level of measured inequality in each of the twenty countries. The figures are provided for visualizing the role of weighting procedures for (bilateral) country inequality rankings. The figures are not intended to mislead the reader into inequality comparisons for a particular country along the dimension of one of the three ingredients. Such comparisons are meaningless, as changing one of the ingredients gives a new measure.

[^9]Figure 2a. Decomposition of mean logarithmic deviation

Note. Grey lines refer to size weighting, black lines to needs weighting. Solid lines indicate mean logarithmic deviation; short dashed lines the within-group inequality component; long dashed lines the between-group inequality component. Own calculations based on LIS 2000 data.

Figure 2b. Decomposition of Theil index

Note. Grey lines refer to size weighting, black lines to needs weighting. Solid lines indicate Theil index; short dashed lines the within-group inequality component; long dashed lines the between-group inequality component. Own calculations based on LIS 2000 data.

Figure 2c. Decomposition of half the square of the coefficient of variation

Note. Grey lines refer to size weighting, black lines to needs weighting. Solid lines indicate half the square of the coefficient of variation; short dashed lines the within-group inequality component; long dashed lines the between-group inequality component. Own calculations based on LIS 2000 data.

For matters of space, we will confine our research to one bilateral case study. Our case study involves a comparison of France and Sweden for $G E(0)$. Readers who want to perform analogous bilateral country comparisons may consult the decomposition results summarized in Tables A2 together with Tables A3a-A3c in the Appendix. For France and Sweden, Table 4 conveys point estimates of mean logarithmic deviation, the inequality between- and withingroup component at two levels of household size economies, i.e. $\theta=0.5$ and $\theta=0.25$. For $\theta=0.5$ point estimates from both weighting schemes indicate more inequality in France. The result, however, reverts for $\theta=0.25$. At the same time, the between (within) component explains a larger fraction of total inequality in Sweden (France). In case of size (needs) weighting and $\theta=0.5$, it makes up 18.49 percent ( 18.57 percent) of overall inequality in

Sweden as opposed to 7.20 percent ( 6.73 percent) in France. For $\theta=0.25$, the between-group component in Sweden explains 32.47 percent ( 34.11 percent) of total inequality for size (needs) weighting while the respective number for France is 11.93 percent (14.17).

Table 4. Inequality indices for France and Sweden

|  | State | $\theta=0.50$ |  | $\theta=0.25$ |  |
| :---: | :---: | :---: | :---: | :---: | :---: |

|  |  |  |  |  |  |
| GEW(0) | FR | 10.06 | 10.54 | 10.06 | 10.79 |
|  |  | $(92.80)$ | $93.27)$ | $(88.07)$ | $(85.83)$ |
|  | SE | 7.37 | $(8.01$ | 7.37 | 8.33 |
|  |  | $(81.51)$ | $(81.43)$ | $(67.53)$ | $(65.89)$ |

Note. GE(0) is mean logarithmic deviation; GEB(0) is between group inequality; GEW(0) is within group inequality. $\theta$ denotes the equivalence-scale elasticity. In parentheses: Contribution in percent to total inequality. All indices multiplied with 100. Own calculations based on LIS 2000 data.

These patterns in combination with the further disaggregated statistics in Table 5 make the effects of weighting schemes on country rankings intelligible. Particularly, Table 5 provides the determinants of the mean logarithmic deviation and its within and between component decomposed by the nine household types.
Altogether, Table 5 consists of three panels. The first panel contains household-type specific measures that are invariable to equivalence scale elasticity, i.e. household sizes, size-weighted population shares and household types’ mean logarithmic deviations. Comparing the two countries, there are two obvious dissimilarities. First, in Sweden the population share of childless single adults is particularly high ( 25.68 percent in Sweden vs. 14.21 percent in France). Second, household-type specific mean logarithmic deviations are always higher in France compared to Sweden, while the quantitative variation in subgroup indices is more pronounced for Sweden. Again, Swedish childless single adults stick out with a subgroup index far above the other household types' indices.
The second (third) panel of Table 5 gives household-type specific equivalence scales, needs weighted population shares and mean equivalent incomes relative to the population-wide means when $\theta=0.5$ ( $\theta=0.25$ ). The latter statistic reveals another remarkable difference between France and Sweden. It concerns the economic situation of childless single adults: Average equivalent income of childless single adults falls far below the Swedish average. For

France, the gap is substantially smaller. Both effects combined it is not surprising that, compared with size weighting, a higher population share of childless single adults in case of needs weighting (particularly at high levels of household-size economies) has other implications for the within- and between-group component in Sweden compared to France: In Sweden, both effects have a quantitatively stronger positive effect on measured inequality when switching from size to needs weighting. As a result, size and needs weighting lead to (in)consistent findings when household-size economies are low (high).

Note. $n$ denotes household size; $q_{k}^{t}$ is the fraction of the population living in type $k$ households according to weighting scheme $t$. $\mu_{k}^{t}$ is mean equivalent income of type $k$ household according to weighting scheme $t ; \mu^{t}$ is mean equivalent income according to $t$. $G E_{k}(0)$ is mean logarithmic deviation in subgroup $k$. $\theta$ denotes the equivalence-scale elasticity; In parentheses and in italics: Fraction of total inequality. All indices multiplied with 100. Own calculations based on LIS 2000 data.

## 7 Conclusion

There is a broad consensus regarding the general need to adjust household incomes for differences in household needs when research involves the distribution of income and living standards in a society. The adjustment is achieved by dividing household incomes by equivalence scales, deflators that capture household economies. On the contrary, the modus operandi concerning the weighting of household units is open to debate. When a population of differently-sized households is transformed into an artificial equivalent population, two alternative conversion schemes have been advocated: a weighting by household size and by needs.

We have provided cross-country personal-income inequality rankings derived from size- and needs-weighted distributions. Our examination revealed that cross-country inequality rankings are sensitive to weighting for reasonable levels of within-household size economies. For example, when the square-root equivalence scale is applied, Kendall's rank correlation of size and needs weighted country rankings based on the Theil index is 0.905 . Performing a twocountry inequality decomposition case study we isolated the channels that lead to differences in size and needs weighted country inequality rankings. The identification of these channels turned out to be a complex yet doable task.

We want to point out that beyond cross-country inequality rankings it may well be that also country welfare (measured by average equivalent income) or poverty rankings, as well as the assessment of the distributional effects of tax-transfer systems, are sensitive to the choice between the two weighting-types we have studied here.

Finally, some remarks on the advantages and disadvantages of the two weighting schemes. In applied inequality analyses, size-weighted distributions of equivalent incomes usually form the underlying database, maybe because size weighting is seen as the 'natural' procedure. However, it is not innocuous from a normative perspective. Ebert and Moyes (2003) study the implications of two normative principles, 'reference independence' and the 'between-type-transfer-principle, ${ }^{21}$ Reference-type-independence restricts admissible equivalence scales to be independent-of-base. For meeting both criteria, equivalent incomes must further be weighted by a factor that is equal (proportional) to the underlying equivalence scale, as this type of conversion, i.e. needs weighting, leaves the total equivalent income in the distribution

[^10]of equivalent adults unaltered. On the contrary, in a size weighted distribution transfers between differently sized household types can change total equivalent income.
Albeit the appealing properties of needs weighting, the information content of a distribution of equivalent adults is open to debate. Particularly, weighting by needs violates the principle of normative individualism, according to which any person is considered as important as any other. Instead, a four member household in a needs weighted distribution has only twice the weight of a one member household when the square-root scale is applied. The discomfort with needs weighting is expressed in several articles. For example, as O’Higgins et al. (1990: 26) stressed and Podder and Chatterjee (2002: 11) later reechoed: "Equivalent adults do not exist, unlike families or individuals, although a family or an individual may have an equivalent income." Bruno and Habib (1976: 63) express a similar discomfort using the words of one of their colleagues, Yoram Ben-Porath: "If it costs less to make a person happy it still does not make him less a person."

Indeed, Shorrocks (2004) identifies a basic dilemma: the two basic criteria - the 'equity preference' condition and the 'compensation principle’ - are fundamentally incompatible (except in particular circumstances), ${ }^{22}$ so that one has to be discarded. He favors the compensation principle, "thereby vindicating the traditional method of dealing with heterogeneous samples," i.e. constructing a size weighted distribution of equivalent incomes (Shorrocks 2004: 193). Analogous to Ebert and Moyes (2003), for inequality and welfare comparisons to be well defined equivalence scales must be independent of base.

Note. $N$ denotes non weighted number of observation. "Pop. share" is the fraction of working sample living in a household type (weighted by LIS frequency weights; in percent). "Av. income" denotes mean disposable income (weighted by LIS frequency weights). See Table A1 for country code definitions. Own calculations based on LIS 2000 data.

Note. Point estimates and, in parentheses and italics, 95 percent bootstrap confidence intervals. All indices multiplied with 100. See Table A1 in the Appendix for definition of country codes. Own calculations based on LIS 2000 data.

[^0]:    ${ }^{1}$ Weighting by size, for example, is recommended by the World Institute for Development Economics and Research (undated) and also by the Luxembourg Income Study (2009).

[^1]:    ${ }^{2}$ Or by a factor that is proportional to an equivalence scale.
    ${ }^{3}$ Size weighted total equivalent income increases when income is redistributed from the less efficient (onemember) to the more efficient (multi-member) household unit.

[^2]:    ${ }^{4}$ The required information includes expenditures and time use together with the quantity/quality of domestic production and the intra-family allocation.
    ${ }^{5}$ See Blundell and Lewbel (1991), Browning (1992), Nelson (1993), Dickens et al. (1993), Pashardes (1995) for reviews of related literatures.

[^3]:    ${ }^{6}$ See also van den Bosch (2001) for an excellent in-depth review of the literature.
    ${ }^{7}$ Such phenomena include: social desirability of responses, sample-selection bias, lack of attitude concerning the research question, anchoring effects, etc. (see Tanur 1992 or Sudman et al. 1996 for reviews).
    ${ }^{8}$ For an overview of hurdles related to survey techniques and a conservative assessment of the information content of survey data see Bertrand and Mullainathan (2001).
    ${ }^{9}$ With an income dependent equivalence scale, country rankings may hinge upon the selection of the reference type (a 1-member household in our case). This would have urged us to perform our analysis for nine different reference-household types.

[^4]:    ${ }^{10}$ The underlying LIS datasets from years 1999/2000 are surveyed in Table A1 in the Appendix.
    ${ }^{11}$ We use the LIS variables 'd4' and 'd27' to distinguish adults from children, where 'd27' gives the number of household members of age below 18 and 'd4’ denotes the total number of household members.
    ${ }^{12}$ We provide the non-weighted number of observations to give the reader a clear picture of the actual numbers of observations provided by LIS. Of course, all calculations are conducted on the basis of weighted distributions. ${ }^{13}$ For the exact definition of disposable household income see Luxembourg Income Study (2006), and for its cross-country comparability Burkhauser et al. (1996) and references therein.

[^5]:    ${ }^{14}$ In the technical description we assume that ties in the country ranking do not exist.

[^6]:    ${ }^{15}$ Our analysis requires a bootstrapping over 20 countries, 20 equivalence scales and two weighting schemes. At the same time the LIS computers' working space is limited. Although the LIS team provided us with extra computer capacity for our analyses, we had to confine ourselves to 100 bootstrap repetitions.
    ${ }^{16}$ While LIS frequency weights and households' needs/size weights are not accounted for in the bootstrap, they are always included when inequality indices (and related statistics) are derived. For technically equivalent empirical applications see Athanasopoulos and Vahid (2003) or Bönke and Schröder (2011).

[^7]:    ${ }^{17}$ See: http://www.lisdatacenter.org/data-access/key-figures/inequality-and-poverty/
    ${ }^{18}$ See: http://www.oecd.org/LongAbstract/0,3425,en_2649_33933_35411112_119669_1_1_1,00.html

[^8]:    ${ }^{19}$ Due to hardware restrictions, we have derived the rank correlations from the observed inequality indices rather than from a bootstrap-based ranking.

[^9]:    ${ }^{20}$ Results can be provided by the authors upon request.

[^10]:    ${ }^{21}$ According to reference independence, welfare or inequality comparisons should not be affected by a change of the reference household type. According to the between-type-transfer-principle, an income transfer reducing the differences in living standards (equivalent incomes) between two households and not affecting the households’ ranking by living standards, should always lead to a social improvement (cf. Ebert and Moyes 2003: 331).

[^11]:    ${ }^{22}$ According to the equity preference condition, welfare rises (and inequality falls) when income is transferred to those worse-off. According to the compensation principle, welfare and inequality remain unchanged "whenever a member of the population is replaced by another with the same standard of living, but different personal characteristics" (Shorrocks 2004: 194).
