Limitations of stabilizing effects of fundamentalists: facing positive feedback traders

Michael Baumann, Michaela Baumann, and Alexander Erler

Abstract
The authors analyze financial interactions between fundamentalists and chartists within a heterogeneous agent model, focusing on the role of fundamentalists stabilizing prices. In contrast to related studies, which are based on simulations and calculations, they analytically prove that the presence of fundamentalists is not sufficient to avoid asset price bubbles. The behavior of trend followers with bounded leverage can result in exploding prices irrespective of fundamentalists' investment decisions. They derive upper boundaries for positive feedback traders' initial investment necessary to avoid exploding prices. In order to stabilize stock/asset markets, intervention measures might be helpful.

1 Motivation

Financial market bubbles have repeatedly caused macroeconomic threats, a very prominent example of which was the dot-com bubble. While misguided economic policies are typically among the usual suspects in trying to understand such aberrations, an important strand of the literature focuses on the question of whether specific behavior of market participants is responsible for price bubbles. In particular, heterogeneous agent models (HAMs) analyze how both chartists and fundamentalists are able to determine asset price movements (Hommes, 2006a).

Chartists, i.e., for instance, trend followers, trade based only on information about the price process, that is, they assume that all relevant information has already been priced in (Graham et al., 1934). In contrast, fundamentalists have some fundamental value in mind and trade based on perceived over- or undervaluation of the underlying asset. Trend followers magnify the current trend, either positively or negatively, because their trading is based on the philosophy that the greater the absolute value of the slope of the price process, the more should be bought or sold (Covel, 2004). Fundamentalists, in contrast, buy or sell when the price is below or above the fundamental value, thereby pushing the asset price toward its fundamental value. Traders act out of self-interest with the intention of making a profit, and give little thought to how their actions will impact prices. As a consequence of the two different investment strategies, the presence of chartists can cause exploding prices (De Long et al., 1990b), whereas fundamentalists are associated with a stabilizing influence on assets. Thus, the following question arises:

*Are the balancing effects of fundamentalists strong enough to compensate for the destabilizing impacts of chartists?*

Heterogeneous agent models are increasingly employed in search of an answer to this question (Gaunersdorfer and Hommes, 2007; Hommes, 2002; Lux, 1995, 1998; Lux and Marchesi, 1999, 2000). These studies provide useful explanations for many stylized facts, including excess volatility, high trading volume, temporary bubbles, trend following, sudden crashes, mean reversion, clustered volatility and fat tailed distribution returns.¹ The models typically use bounded rational agents, (imperfect) heuristics or rules of thumb, and nonlinear dynamics (which might be chaotic). Some studies find that the stabilizing effects of fundamentalists are not necessarily strong enough to stabilize markets (Hommes, 2006a). However, the results are usually obtained via simulations and are not analytically proven (Hommes, 2006a,b).

¹For an excellent overview regarding HAMs see the work of Hommes (2006a).
An exception is the work of De Long et al. (1990b) which investigates the effect of positive feedback traders and informed speculators, who evaluate and consider the needs of the other market participants, especially the growing needs of the positive feedback traders, in a three-period market model facing fundamentalists. De Long et al. (1990b) show that the interaction of these two trader types pushes the price away from the fundamental value under specific assumptions and despite the fundamentalists’ stabilizing behavior. Our analysis differs from De Long et al. (1990b) in that we do not investigate how two types of traders—positive feedback traders and informed speculators—jointly push up the price but instead look only at trend followers, nor do we assume a predetermined end of the market. This leads us to a second question:

*Is it possible to analytically prove that chartists’ behavior can lead to exploding prices irrespective of fundamentalists’ compensatory effects?*

The main contribution of our paper is a mathematically rigorous proof that chartists’ behavior—specifically, the strategy of linear feedback traders is without rational expectations, without information about the market (e.g., fundamental value, trading volume, or even prices), and with bounded leverage—can overcome the stabilizing effects of traders with rational expectations of the fundamental value and without liquidity constraints. Put differently, prices explode because the stabilizing effects of fundamentalists are outweighed by linear feedback traders. Unstable price developments are the result, which in turn increase the likelihood of a financial bubble. As shown in the proof, thresholds for model-inherent values can be specified that make certain the occurrence of a bubble. Furthermore, there are certain values of external parameters that allow the thresholds of the inherent values to be met. The analysis reveals that even fundamentalists without any liquidity constraints and with perfect information about the price, the fundamental value, and the market’s characteristics are not sufficient to stabilize a very simply constructed market based on (excess) demand if the feedback trader’s initial investment is large enough. The main explanation for this behavior given in our work is that fundamentalists respond always one period later than chartists. This property is analytically shown. When fundamentalists could forecast and compensate the demand of the chartists, markets would always be stable. However, fundamentalists have to wait for the actions of the chartists and can respond just with a delay of one period, giving the chartists the chance to rise prices, make profit, and invest even more.

Further important work on the topic of interactions between fundamentalists and chartists is done by Westerhoff (2004) who uses a very similar
pricing rule as we do. The main difference is that the chartist’s demand is assumed to be linear in the slope of the log-price. This possibly leads to a possibly unbounded leverage, i.e., the ratio between assets and equity can go to infinity. In Westerhoff (2004) it is shown that price dynamics become unstable when the ratio between the chartist’s and the fundamentalist’s demand parameter becomes too large. However, in that model it is not clear whether the chartist can follow the “linear in the slope of the log-price” trading rule at all because the leverage is possibly unbounded.

We explain the problem of unbounded leverage in another setting: Let’s have a look at doubling up strategies for roulette. It is easy to see that such a roulette strategy will almost surely lead to a positive payoff: the gambler bets on red until red wins and doubles the bet each time black wins. The problem is that the gambler might run out of money before realizing the gain.

In this analysis, the leverage of the chartist is bounded by the so-called feedback parameter $K$, which allows us to assume that the chartist can trade according to the chartist’s rule, producing a bubble. That means, our analysis shows that regardless of the chartist’s bounded leverage, technical trading might destabilize financial markets. Westerhoff (2004) uses a model where the demand parameters are fixed, i.e., in each point in time the dynamics are, despite of scaling, the same. Since the chartist in our model is a feedback trader with an investment depending on the chartist’s gain, the demand of the chartist might be small for a long time before exploding. Nonetheless, our analysis provides a formula to check already in period zero whether the price path will eventually explode.\footnote{Other work in the area is done by Westerhoff (2006a,b, 2007); Westerhoff and Dieci (2006); Hermsen et al. (2010).}

Other studies close to our work are Franke and Westerhoff (2012, 2016). However, Franke and Westerhoff (2012, 2016) apply an important feature: learning. Using so-called replicator dynamics, the share of chartists and fundamentalists in the model can change, i.e., traders learn from better performing market participants and adjust their rule. In that setting several stylized market facts can be reproduced. By contrast, we are less interested in stylized facts but more in the stability analysis of the market. In a market where fundamentalists can switch to chartist rules when this is more profitable, the likelihood of price bubbles is even higher. When there is an upwards trend in the chart, chartists will make profit and fundamentalists will switch to chartist rules. Thus, there are less fundamentalists who disinvest from the asset and more chartists who invest in the asset: so even more capital will be invested and prices will rise faster. In our model, we explicitly do not
allow traders to switch because our aim is to show that not the replicator
dynamics (all fundamentalists become chartists when prices go up) leads to
the asset price bubble but the trading rules itself does. Put differently, we
show that prices might explode even when the shares of the traders are fixed
and the leverage of the chartists is bounded.

The field of applied mathematics has many new results concerning tech-
nical trading strategies (Barmish and Primbs, 2011, 2016; Baumann, 2017;
Baumann and Grüne, 2016, 2017; Primbs and Barmish, 2013, 2017). For
example, the performance properties of chartist strategies have been proven
and explanations given for why it is reasonable to trade according to a feed-
back strategy. In contrast to the feedback trading literature, where the price
taker property is usually presumed, we study the effects of trading strategies
in an HAM that displays phenomena caused by (excess) demand (Baumann,
2015).

The paper is organized as follows: Section 2 explains the price model as
well as the investment strategies of feedback traders and fundamentalists.
Section 3 answers the main question of the paper, that is, whether the pres-
ence of fundamentalists is sufficient to stabilize the market and Section 4
provides ideas for future work and concludes the paper.

2 Model Structure

The model consists of a one asset market and is populated with two types of
heterogeneous agents—fundamentalists and chartists. Their interaction with
the market maker is illustrated in Section 2.1. Section 2.2 presents the price
process in the interactive market model. Sections 2.3, 2.4, and 2.5 introduce
the traders and their expectations. For simplification of the analysis we
assume that there is only one feedback trader, that is we treat all existing
feedback traders as one representative feedback trader. There is indeed no
difference between one feedback trader with an initial investment $I_C^0$ and
fixed $K$, see Section 2.3, and $n$ feedback traders with initial investments $I_C^0/n$ and
the same $K$. That is, for the feedback traders this summarization is
without loss of generality.

2.1 Timeline

At the beginning of each period $t \in \{0,1,\ldots,T\}$, each agent $\ell \in \{C,F\}$,
where $C$ is the feedback trader (chartist) and $F$ the fundamentalist, decides
how to invest based on the respective investment strategy, where $T$ is un-
known or even $\infty$. Each investment strategy $I_\ell^t$ is guided by a different
heuristic (rule of thumb). Based on the strategy chosen, each agent then allocates his or her financial resources among the asset market. The trader is aware of historical market data and of expectations regarding future fundamental values $\mathbb{E}[f_{t+1}]$. The resulting buying and selling decisions, denoted by $D^\ell_t$, are cleared by a market maker who adjusts asset prices according to (excess) demand. After the traders have observed the price change $\Delta p_t$, and hence their own gains or losses $\Delta g^\ell_t$ in the recent period, they use this information in making their next investment decision.

Based on this trading behavior the price model is constructed. The timeline of the traders’ and the market maker’s decisions and interactions is shown in Figure 1. For all processes $\alpha_t$ we set $\Delta \alpha_t = \alpha_t - \alpha_{t-1}$ as the change of the underlying process, e.g., $\Delta g^\ell_t$ is the period profit while $g^\ell_t$ is the overall gain/loss of trader $\ell$.

![Figure 1: Timeline of the traders’ and the market maker’s decisions and interactions with $\Delta g^\ell_t = I^\ell_{t-1} \cdot \frac{\Delta p_t}{p_t}$](image)

### 2.2 Price Process for the Interactive Market Model

In feedback trading literature, price is usually determined through a certain price process, for example, geometric Brownian motion (GBM), which is exogenously given (Barmish and Primbs, 2016). This implies that the traders are not able to influence the price. To avoid this price taker property, which is a strong restriction of every market model, agent-based price models have evolved in the academic economics literature (Hommes, 2006a). According to these models, the price is a function of traders’ investment decisions. We denote the sum of all traders’ demand at time $t$ with $D_t = \sum_\ell D^\ell_t$. Based on
the idea of interacting agents, Baumann (2015) constructs a pricing model that fulfills the law of (excess) demand, very similar to the following rules:

(i) \( p_{t+1} = p_t \) if \( D_t = 0 \)
(ii) \( p_{t+1} \to \infty \) if \( D_t \to \infty \)
(iii) \( p_{t+1} \to 0 \) if \( D_t \to -\infty \)
(iv) \( p_{t+1} \) strictly increasing in \( D_t \)

In fact, Baumann (2015) uses the change of investment \( \Delta I_t \) instead of the demand \( D_t \). Based on our simulations, use of the change of investment instead of the demand (i.e., the buying/selling decision) affects the proposition of this paper only quantitatively, not qualitatively.

For simplification, we assume an infinite supply, and thus the law of supply and demand reduces to a law of (excess) demand. Infinite supply is, for example, given in artificial markets for synthetic assets, betting slips, etc. These assets are produced by the market maker without any restriction. Thus, the market maker can definitely clear the market. In modern stock exchanges, also shares of funds etc. can be bought from investment bankers (market makers) at any amount for a price set by the market maker. It follows that the market maker sets the new asset price according to the asset demand only.

This model, which is in a sense a natural generalization of the GBM (proven in Baumann, 2015), in its general form is given by

\[ p_{t+1} = p_t \cdot e^{M^{-1}D_t} \]  
\[ = p_0 \cdot e^{M^{-1}B_t} \]

where \( M > 0 \) is a scaling factor expressing the trading volume of the underlying asset and \( B_t = \sum_{\tau=0}^{t} D_\tau \) is the sum of all demands up to time \( t \). This pricing rule is similar to that one used by da Gama Batista et al. (2017). Unless otherwise stated, for simplicity \( M \) is set to \( M = 1 \). The pricing model is finally closed through the market maker (Hommes, 2006b). As common practice, the market maker acts as a privileged trader that sets prices according to (excess) demand (see Figure 2) and hence ensures market clearing (cf. the role of a broker in stock markets) (Hommes, 2006a). Possible profit making by and survival of the market maker will not be discussed in the work at hand but is an interesting topic for future work.
2.3 Feedback Traders

Barmish and Primbs (2011, 2016); Baumann (2017); Baumann and Grüne (2016, 2017); Primbs and Barmish (2013, 2017) outline a special class of trading strategies based on control techniques, namely, feedback trading. Traders engaged in this sort of strategy are called feedback traders and utilize neither fundamentals nor the absolute asset value in making their investments; they take into account only their own gains and losses. Their strategy thus depends on prices relative to their previous investments, that is, feedback traders are chartists because gains or losses, respectively, are a function of the price but not of any fundamental value. From a control theoretic point of view, feedback traders treat the price like a disturbance variable and their strategy needs to be robust to this disturbing influence. In calculating a certain trader’s gain, the market maker takes into account the trader’s investment and the asset price. The price is a function of all traders’ investment; see Section 2.2 and, especially, Figure 2. Therefore, in case of feedback traders it holds, that investment decisions and gains are determined in a feedback loop.

One specific feedback strategy, discussed by Barmish and Primbs (2011, 2016); Baumann (2017), is the positive linear feedback strategy

\[ I_t^C := I_0^C + K \cdot g_t^C \]  

where the linear feedback trader calculates the own investment \( I_t^C \) at time \( t \) as a linear function of the gain/loss function \( g_t^C \) using the initial investment \( I_0^C > 0 \) and a feedback parameter \( K > 0 \). We rely on the positive linear
market maker

\[ g_t^C = g_{t-1}^C + I_{t-1}^C \cdot \frac{p_t - p_{t-1}}{p_{t-1}} \]

\[ I_t^C = I_0^C + K \cdot g_t^C \]

linear feedback trader

Figure 3: Schematic interaction between market maker and linear feedback trader

feedback strategy only because this is the feedback rule possibly causing financial bubbles. In Figure 3 a feedback loop between the gain or loss \( g_t^C \) of a linear feedback trader and the respective investment \( I_t^C \) is shown. By calculating the gain or loss of a specific trader (or group of traders) \( \ell \) via

\[ g_t^\ell = \sum_{i=1}^{t} I_{t-1}^\ell \cdot \frac{p_i - p_{i-1}}{p_{i-1}}, \]

(4)

where \( p_t \) denotes the price process and \( I_t^\ell \) the trader’s investment at time \( t \), it follows that linear feedback traders are trend followers given \( I_t^C > 0 \). (The relative price change \( \frac{p_t - p_{t-1}}{p_{t-1}} \) is called return on investment, and it is a specific feature of the chartist analyzed in the paper at hand that the chartist investment is a function of the return on investment.) A trader is called a trend follower (cf. Covel, 2004) if the trader is buying when prices are rising and selling when prices are falling. Note that the particular demand at time \( t \geq 1 \) is given by

\[ D_t^C = I_t^C - \frac{p_t}{p_{t-1}} \cdot I_{t-1}^C \]

(5)

\[ = I_{t-1}^C + K \cdot I_{t-1}^C \cdot \frac{p_t - p_{t-1}}{p_{t-1}} - \frac{p_t}{p_{t-1}} I_{t-1}^C \]

(6)

\[ = (K - 1) \cdot I_{t-1}^C \cdot \frac{p_t - p_{t-1}}{p_{t-1}}, \]

(7)

whereas \( I_t^C \) denotes the total investment at time \( t \) of feedback trader \( C \). Note
that

\[ \Delta I_t^C = I_t^C - I_{t-1}^C \]  
\[ = I_{t-1}^C + K \cdot I_{t-1}^C \cdot \frac{p_t - p_{t-1}}{p_{t-1}} - I_{t-1}^C \]  
\[ = K \cdot I_{t-1}^C \cdot \frac{p_t - p_{t-1}}{p_{t-1}}. \]

This means that \( D_t^C = \frac{K-1}{K} \Delta I_t^C \) and thus \( B_t^C = \frac{K-1}{K} I_t^C \). If \( K \neq 1 \), the trader is not only a buy-and-hold trader, but is really buying and selling. We can rewrite

\[ D_t^C = K B_t^C \cdot \frac{p_t - p_{t-1}}{p_{t-1}}. \]

Now, we always assume \( K > 1 \), i.e., a trader who is buying more and more when making profit (because this is the interesting case for bubble investigation).

Rising prices lead to increasing gain for the linear feedback trader if \( I_t^C > 0 \) and, thus, the trader buys. Analogously, falling prices lower the gain and the trader sells.

In this section, markets with purely linear feedback traders are studied, that means \( I_\ell^t \equiv 0 \) for all \( \ell \neq C \). In this case, the feedback-based investment strategy is given by

\[ D_0^C = I_0^C > 0, \]
\[ D_1^C = (K - 1) \cdot I_0^C \cdot \left( e^{M^{-1} I_0^C} - 1 \right), \text{ and} \]
\[ D_t^C = (K - 1) \cdot I_{t-1}^C \cdot \left( e^{M^{-1} D_{t-1}^C} - 1 \right), \quad t \geq 2. \]

This leads us to the following lemma.

**Lemma 1.** If in our market maker model there is only one trader, a linear feedback trader \( C \), trading with the market maker, the price dynamics (for \( t \geq 2 \)) is:

\[ \Delta B_t^C = K B_{t-1}^C \cdot \left( e^{M^{-1} \Delta B_{t-1}^C} - 1 \right) \]

Baumann (2015) shows in a very similar model that in the event only one feedback trader \( C \) is acting on the market with the price process described in Section 2, it holds that

\[ I_t^C > 0 \quad \forall t, \]
\[ D_t^C > 0 \quad \forall t, \quad \text{and} \]
\[D_t^C > D_{t-1}^C \Rightarrow D_{t+1}^C > D_t^C.\] 

We prove this in the remainder of this section.

**Lemma 2.** If the investments of all other traders are zero, the investment \(I_t^C\) and the demand function \(D_t^C\) of the linear feedback trader are positive.

**Proof.** The lemma is proven by induction. Because of \(I_0^C > 0\) and \(e^{M-1}I_0^C > 1\), the initial inequality \(D_1^C > 0\) is true. It follows \(I_1^C = I_0^C(e^{M-1}I_0^C - 1) + D_1^C > 0\). The induction step follows, as \(e^{M-1}D_{t-1}^C > 1\) and \(I_t^C = I_{t-1}^C(e^{M-1}D_{t-1}^C - 1) + D_t^C > 0\). \(\square\)

It holds that \(D_t^C > 0\) because of \(I_0^C > 0\). This means that feedback traders’ investment increases prices and thus also their gain, leading again to positive buying decisions and so on. But this does not necessarily have to end in a bubble. We say that a bubble occurs if \(\exists t^* : \Delta \ln p_{t+1} > \Delta \ln p_t \ \forall t \geq t^*\). Note that if there are only chartists it holds that \(p_t = p_{t-1}e^{M-1}D_{t-1}^C\), i.e., \(\Delta p_t = p_{t-1}(e^{M-1}D_{t-1}^C - 1)\). Two typical demand paths can be identified in the scenario where only one feedback-based trader is acting on the market. The two paths are shown in Figure 4 and Figure 5 where the asset price \(p_t\) is indicated with a solid line and the feedback trader’s investment with a dashed one. If \(I_0^C\) lies below a specific threshold, \(I_t^C\) converges (Figure 4). If it is above this threshold, the investment explodes (Figure 5). Baumann (2015) provides a non-closed formula determining upper boundaries for this threshold. Specific values for this threshold can be derived through a simulation like that one in Figure 4 and Figure 5 and by algorithmically localizing the threshold. That means, the demand function and, thus, the price can converge to some value.

**Theorem 3.** If the investments of all other traders are zero and \(\exists t^* \in \mathcal{T} : \Delta D_t^C > 0\) then 
\[\Delta D_t^C > 0\] holds for all \(t \geq t^*\). That means, the bought amount of stocks \(D_t^C\) of the feedback trader is strictly increasing for all \(t \geq t^*\).

**Proof.** The induction step 
\[D_t^C > D_{t-1}^C \Rightarrow D_{t+1}^C > D_t^C, \ t \geq 1,\] has to be shown. This is true because of 
\[D_{t+1}^C > D_t^C \Leftrightarrow I_t^C \cdot \left(e^{M-1}D_{t-1}^C - 1\right) > I_{t-1}^C \cdot \left(e^{M-1}D_{t-1}^C - 1\right),\]
$D^C_t > 0$ from which it follows $\Delta I^C_t > 0$, and the induction hypothesis.

This is important as it is shown that, together with the results of Section 3, the price explosion effects of feedback traders that would possibly occur in absence of fundamentalists can be compensated by fundamentalists at least to a certain degree.

There remains the question why a trader should follow such a linear feedback trading strategy. The answer lies in some performance properties of feedback rules, especially of combinations of different linear feedback rules. For the performance analysis of feedback rules we refer to the work of Barmish and Primbs (2011, 2016); Baumann (2017); Baumann and Grüne (2017).³

![Figure 4: A typical situation in a market involving a feedback trader. The price and the feedback trader’s demand converge, i.e., the feedback trader’s initial investment $I^C_0$ is below a specific threshold. Parameters: $p_0 = 1, M = 1, T = 250, I^C_0 = 0.191, K = 2$.](image_url)

### 2.4 Fundamentalists

As explained in Section 1, fundamentalists buy when the price is below the fundamental value $f_t > 0$ and sell when the price is above the fundamental

---

³In the literature, a specific superposition of two linear feedback rules—the so-called simultaneously long short (SLS) strategy—is analyzed. It is shown that the SLS rule offers an arbitrage opportunity when prices are smooth and a positive expected gain when prices are governed by geometric Brownian motions, by Merton’s jump diffusion model, and by many other price models.
value. If, for example, the fundamental value is below the asset price, fundamentalists conclude that the price decreases in the long run, not necessarily in the next step. So they possibly do not sell as much that their investment becomes negative, but they reduce their investment. Thus, it is of particular interest how much fundamentalists buy or sell in the respective cases. For deterministic fundamental values $f_t$, i.e., the fundamental value is a function in $t$, one way of determining the demand rate of the fundamentalists is

$$D_t^F = M \cdot \ln \frac{f_{t+1}}{p_t}$$

(22) (cf. Drescher and Herz, 2012). In this case, fundamentalists do not need to estimate the fundamental value because it is fixed and certain for the future period. Note that we treat all fundamentalists as one representative fundamentalist. Traders following this demand rule could be called strong fundamentalists because their investment strategy could push the price back to its fundamental value at any time.

**Theorem 4.** If the strong fundamentalist is the only trader buying/selling at time $t$, then for any $p_t > 0$ and $f_{t+1}$ it follows:

$$p_{t+1} = f_{t+1}$$

(23)
Proof.

\[ p_{t+1} = p_t \cdot e^{\ln \frac{f_{t+1}}{p_t}} \]  
\[ = p_t \cdot \frac{f_{t+1}}{p_t} \]  
\[ = f_{t+1} \]  

Section 2.5 presents the case of a fundamentalist trading based on a distorted fundamental value. It turns out, however, that this distortion does not affect the general behavior of the market model. Note that the leverage of the fundamentalists—in contrast to the chartists—is assumed to be unbounded, i.e., the fundamentalists can buy and sell whatever they want independent of their account value.

2.5 Expectations and Noise

Some types of traders, for example informed speculators (De Long et al., 1990b), base their trading decisions on rational expectations. Is this the case for feedback traders and fundamentalists?

In general, for feedback traders and trend followers, the answer is “no,” as they only assume the existence of a trend. For example, based on the current slope of asset price development \((p_t - p_{t-1})\) they forecast the future direction of the asset. However, fundamentalists are assumed to have rational expectations (see, e.g., Drescher and Herz, 2012). Generally, they pursue the strategy

\[ D^F_t = M \cdot \ln \frac{\mathbb{E}[f_{t+1} | F_t]}{p_t} \].

A casual observation of real markets makes clear that price fluctuations are not always purely rational. There is always noise and uncertainty in the market, a factor considered essential by many economists (see, e.g., Black, 1986; De Long et al., 1990a). Some reasons for noise include that traders make mistakes, trade on unreliable (noisy) information, or simply enjoy trading and are not overly concerned with being rational about it.

Here, we do not assume that traders are making mistakes, as this could lead to unsystematic behavior, i.e., we do not take noise traders into account (a market with a linear feedback trader and a noise trader is analyzed by Baumann (2015)). Furthermore, both feedback traders and fundamentalists do follow a specified strategy. Thus, the only way noise could enter the market is
through noisy information. However, the traders’ investments as well as the price, announced by the market maker (see Figure 1), are not distorted. The only information that could be noisy is that about the fundamental value. In this case, the fundamentalist has to estimate $f_{t+1}$ at time $t$ and trades according to $\mathbb{E}[f_{t+1}|\mathcal{F}_t]$. Since it is unreasonable that $|f_{t+1} - \mathbb{E}[f_{t+1}|\mathcal{F}_t]|$ becomes arbitrary large, i.e., that the estimation of the fundamental value is totally wrong, but exploding prices imply $|p_t - f_t| \rightarrow \infty$, the effects of noisy information do not play a decisive role. Therefore, we a priori consider $f_t$ a deterministic fundamental value.

3 Proof of Limitations of Fundamentalists’ Stabilizing Effects

In this section we demonstrate analytically and mathematically rigorously that fundamentalists are not always able to stabilize markets through their trading actions. We inductively prove, in contrast to simulations, that effects of linear feedback traders dominate those of fundamentalists and destabilize markets.

Since we have already defined the pricing model and the traders, the next task is to check whether fundamentalists defined according to Section 2.4 are able to stabilize the price when trading simultaneously on the market with linear feedback traders following Section 2.3. To simplify the notation, we set $f_t \equiv 1$. This is one special case, but when we can show the destabilizing effects of feedback traders’ investment strategy for this case, it proves that fundamentalists do not always have market stabilizing effects. The proof proceeds without using technical trading restrictions.

The two trader types linear feedback trader $C$ and fundamentalist $F$ are suitable for analyzing the question of destabilizing effects of linear feedback traders because if it turns out that prices explode for appropriately chosen parameters $I_C^*$ and $K$ of linear feedback traders even when acting on a market with fundamentalists, who are employing an investment strategy that could bring prices close to the fundamental value at every point in time. Thus, it is strong evidence that chartists’ rules, in this case the linear feedback strategy, are able to overcome the effects of strong fundamentalists in various market situations. Why it is enough to consider only linear feedback traders and fundamentalists and no other type of traders, some of which are presented by Ivanova et al. (2014), becomes obvious when taking into consideration that if feedback traders’ investment goes to infinity which means prices explode, then also the absolute value of fundamentalists’ investment goes to
Figure 6: A typical situation in a market involving a feedback trader and a fundamentalist. The price and the feedback trader’s demand converge, i.e., the fundamentalist’s effects predominate since the trend follower’s initial investment $I_0^{C}$ is below a specific threshold. Parameters: $p_0 = 1, M = 1, T = 25, f_t = 1, I_0^{C} = 5.19, K = 2$.

infinity. Thus, compared to the exploding investments of feedback traders and fundamentalists, the relatively small investment of other possible traders may be neglected at least for our analysis.

Trend followers invest a lot when prices rise strongly and fundamentalists disinvest a lot when the price greatly exceeds the fundamental value, i.e., the investment of trend followers goes to infinity and that of fundamentalists goes to minus infinity. For traders who neither predicate their investment on the distance of fundamental value and price nor on the slope of the price it is unreasonable that their investment goes to (minus) infinity. Simulations reveal two typical price developments (see Figure 6 and Figure 7).

In Figure 6, fundamentalists’ effects predominate and the price stabilizes around the fundamental value. In Figure 7, however, market development is not that obvious. At a first glance, the figure might suggest that prices explode. But as the simulation software reaches its limits, it becomes unclear whether or not prices level out in these simulation scenarios. We therefore need an analytical examination. In cases like those shown in the simulated Figure 7, the proposition of Theorem 8 determines with certainty whether the bought amount of assets of the feedback traders is in fact exploding, or whether this only seems to be the case due to simulation insufficiencies and the portfolio eventually stabilizes, but with a greater amplitude as, for
Figure 7: Another typical situation in a market involving a feedback trader and a fundamentalist. The price and the feedback trader’s demand diverge, i.e., the feedback traders’ effects predominate since the feedback trader’s initial investment $I_C^0$ is above a specific threshold. Parameters: $p_0 = 1, M = 1, T = 25, f_t \equiv 1, f_C^0 = 0.521, K = 2$

example, in Figure 6.

To simplify the expressions in the model, we assume in addition to $f_t \equiv 1$ that $p_0 = 1$ in all upcoming equations. This choice is just one possible scaling but does not change the model’s dynamics in general. We define a process $\alpha_t$ as $(\alpha_t)_{t \in \mathbb{Z}} \subset \mathbb{R}$ with $\alpha_t = 0 \ \forall t < 0$. Furthermore, we define the $\Delta$-operator as $\Delta^k \alpha_t := \Delta^{k-1} \alpha_t - \Delta^{k-1} \alpha_{t-1}$, $\Delta^1 \alpha_t := \Delta \alpha_t = \alpha_t - \alpha_{t-1}$, and $\Delta^0 \alpha_t := \alpha_t$. A price process $p_t$ is strictly positive, i.e., $(p_t)_t > 0$ for all $t \geq 0$.

**Theorem 5.** In a market with one feedback trader $C$ and one fundamentalist $F$, it holds:

$$D_F^t = -D_C^{t-1} \quad (28)$$

That means, fundamentalists always compensate what chartists did one period before. Put differently, fundamentalists reactions are one period delayed to the actions of trend followers, and in case of a bubble, the reactions are one period too late.

**Proof.** We calculate:

$$D_F^t = M \cdot \ln \frac{f_{t+1}}{p_t} \quad (29)$$
\[ B_t F = -B_t C - B_t F \] (32)

\[ \Rightarrow B_t F = -B_t C \] (33)

\[ \Rightarrow D_t F = -D_t C \] (34)

With Theorem 5, we can specify the demand of the feedback traders:

\[ D_t C = K \cdot B_t C^t \left( e^{M-1(B_t C^t + D_t F^t)} - 1 \right) \] (35)

\[ = K \cdot B_t C^t \left( e^{M-1(B_t C^t - D_t C^t)} - 1 \right) \] (36)

\[ = K \cdot B_t C^t \left( e^{M-1(\Delta D_t C^t) - 1} \right) \] (37)

**Lemma 6.** If there are exactly one linear feedback trader \( C \) and one fundamentalist \( F \) trading with the market maker, it holds:

\[ \Delta B_t C = K \cdot B_t C^t \left( e^{M-1(\Delta^2 B_t C^t) - 1} \right) \] (38)

Theorem 8 tells us conditions for the feedback trader’s cumulated demand \( B_t C \) for which prices explode. Note that the following implication holds:

**Lemma 7.**

\[ \Delta^k \alpha_t > a \land \Delta^{k+1} \alpha_t > b \Rightarrow \Delta^k \alpha_t > a + b. \] (39)

We obtain this directly from the definition of the delta operator which is equivalent to

\[ \Delta^k \alpha_t = \Delta^{k+1} \alpha_t + \Delta^k \alpha_{t-1}. \] (40)

Note that \( D_t C = \Delta B_t C \) and analogously for the derivatives.

**Theorem 8.** For the demand function resp. for the bought and sold assets of the positive linear feedback trader interacting with a strong fundamentalist on our market model, under conditions

\[ \Delta^3 B_t C > M \cdot \ln 2, \] (41)
\[ \Delta^2 B^C_t > M \cdot \ln 2, \quad \Delta B^C_{t-1} > 0, \quad \text{and} \quad B^C_{t-2} > 0 \quad (42) \]

for some \( t \geq 2 \) it follows that

\[ \Delta^k B^C_{t+k} > M \cdot \ln 2 \quad \forall k \in \{0, 1, 2, 3\}. \quad (45) \]

Theorem 8 is proven by induction in the following.

**Proof.** It is enough to prove the proposition for \( k = 3 \) as all other inequalities can then be derived from the definition of the \( \Delta \)-operator and Lemma 7.

\[ \frac{1}{K} \Delta^3 B^C_{t+1} = \frac{1}{K} (\Delta^2 B^C_{t+1} - \Delta^2 B^C_t) \]
\[ = \frac{1}{K} \left( \Delta B^C_{t+1} - 2 \Delta B^C_t + \Delta B^C_{t-1} \right) \]
\[ = B^C_t \left( e^{M^{-1}\Delta^2 B^C_t} - 1 \right) \]
\[ - 2 B^C_{t-1} \left( e^{M^{-1}\Delta^2 B^C_{t-1}} - 1 \right) \]
\[ + B^C_{t-2} \left( e^{M^{-1}\Delta^2 B^C_{t-2}} - 1 \right) \]
\[ = \left( B^C_t - 2 B^C_{t+1} + \Delta B^C_{t-1} \right) \left( e^{M^{-1}\Delta^2 B^C_t} - 1 \right) \]
\[ - 2 \left( B^C_{t-1} + \Delta B^C_{t-2} \right) \left( e^{M^{-1}\Delta^2 B^C_{t-1}} - 1 \right) \]
\[ + B^C_{t-2} \left( e^{M^{-1}\Delta^2 B^C_{t-2}} - 1 \right) \]
\[ \quad = \left( e^{M^{-1}\Delta^2 B^C_t} - 1 \right) \]
\[ + \Delta B^C_{t+1} \left( e^{M^{-1}\Delta^2 B^C_{t+1}} - 1 \right) \]
\[ + \Delta B^C_t \left( e^{M^{-1}\Delta^2 B^C_t} - 1 \right) \]
\[ - 2 \Delta B^C_{t+1} \left( e^{M^{-1}\Delta^2 B^C_t} - 1 \right) \]
\[ + B^C_{t+2} \left( e^{M^{-1}\Delta^2 B^C_{t+2}} - 1 \right) \]
\[ \quad = \left( e^{M^{-1}\Delta^2 B^C_t} - 2 e^{M^{-1}\Delta^2 B^C_{t+1}} + e^{M^{-1}\Delta^2 B^C_{t-1}} \right) \quad (*) \]
\[ + \Delta B^C_{t+1} \left( e^{M^{-1}\Delta^2 B^C_{t+1}} - 1 \right) \quad (** \quad (61) \]

19
\[ + \Delta B_t^C \left( e^{M^{-1} \Delta^2 B_t^C} - 1 \right) \] (62)

We evaluate these summands separately:

\[ (** \ast \ast) = \Delta B_{t-1}^C \left( e^{M^{-1} \Delta^2 B_{t-1}^C} \left( e^{M^{-1} \Delta^3 B_{t-1}^C} - 2 \right) + 1 \right) \] (63)
\[ = \Delta B_{t-1}^C \left( e^{M^{-1} \Delta^2 B_{t-1}^C} \left( e^{M^{-1} \Delta^3 B_{t-1}^C} - 2 \right) + 1 \right) \] (64)
\[ > \Delta B_{t-1}^C \left( e^{M^{-1} \Delta^2 B_{t-1}^C} (2 - 2) + 1 \right) \] (65)
\[ > 0 \] (66)
\[ (** \ast \ast) = \left( \Delta B_{t-1}^C + \Delta^2 B_t^C \right) \left( e^{M^{-1} \Delta^2 B_t^C} - 1 \right) \] (67)
\[ > 0 + M \cdot \ln 2 \] (68)
\[ (*) = B_{t-2}^C \left( e^{M^{-1} \Delta^2 B_{t-2}^C} + e^{M^{-1} \Delta^3 B_{t-1}^C} + M^{-1} \Delta^3 B_t^C \right) \] (69)
\[ - 2 e^{M^{-1} \Delta^2 B_{t-2}^C} + M^{-1} \Delta^3 B_{t-1}^C + e^{M^{-1} \Delta^2 B_{t-2}^C} \] (70)
\[ = B_{t-2}^C e^{M^{-1} \Delta^2 B_{t-2}^C} \left( e^{M^{-1} \Delta^3 B_{t-1}^C} \left( e^{M^{-1} \Delta^3 B_{t-1}^C} - 2 \right) + 1 \right) \] (71)
\[ > B_{t-2}^C e^{M^{-1} \Delta^2 B_{t-2}^C} \left( e^{M^{-1} \Delta^3 B_{t-1}^C} (2 - 2) + 1 \right) \] (72)
\[ = B_{t-2}^C e^{M^{-1} \Delta^2 B_{t-2}^C} \] (73)
\[ > 0 \] (74)

As a result, we obtain

\[ K^{-1} \Delta^3 B_{t+1}^C > M \cdot \ln 2 \] (75)

and since \( K > 1 \)

\[ \Delta^3 B_{t+1}^C > M \cdot \ln 2. \] (76)

This means, the feedback trader’s bought and sold assets, the demand, the slope of the demand, and the curvature of the demand are strictly greater than \( M \cdot \ln 2 \) for all \( t \geq t^* \) for some \( t^* \). All in all, this is a fast exploding demand, which leads to an equally quickly exploding price.

\[ p_{t+1} = p_t \cdot e^{M^{-1} \cdot (D^F_t + D^C_t)} \] (77)
\[ = p_t \cdot e^{\frac{\ln (1+ \epsilon)}{p_t} \cdot M^{-1} \cdot D^C_t} \] (78)
\[ = f_{t+1} \cdot e^{M^{-1} \cdot D^C_t} \] (79)
Theorem 9. If there are exactly one fundamentalist $F$ and one chartist $C$ (a linear long feedback trader), the price dynamics satisfies for $t > 0$:  

$$p_t = f_t e^{M^{-1}D_{t-1}^C}$$  

(80)

Recall that $D_t^F = \Delta B_t^F$. As an interpretation, note that since $D_t^F = -D_{t-1}^F$, fundamentalists always respond one period later with minus the demand of the feedback traders. Theorem 8 tells us that the feedback trader’s cumulated demand increases, the demand itself increases, and the first and second derivative increase, too. Furthermore, all of these growth rates are bounded from below. Since the fundamentalist’s demand is minus the demand of the feedback trader from one period before, the ratio of the bought and sold amounts is strictly increasing, that is the feedback trader’s exploding effect predominates the fundamentalist’s stabilizing one.

That the conditions for the endogenous variables of Theorem 8, $B_{t-2}^C$, $\Delta B_{t-1}^C$, $\Delta^2 B_t^C$, $\Delta^3 B_t^C$, may be fulfilled for some $t$ (and some parameter assignment) is shown in Table 1 in which the demand development of the feedback trader is listed for $I_0^C = 0.521$, $K = 2$, and $M = 1$. In short, there are exogenous variables that lead to a price explosion. This demonstrates that feedback traders’ effects are able to overcome fundamentalists’ effects.

Table 1: The boxed table entries fulfill the conditions of Theorem 8 for $t = 8$ for which prices explode; market parameters are as in Figure 7 (Note: $\ln 2 \approx 0.6931472 \{p_0 = 1, M = 1, T = 25, f_t \equiv 1, I_0^C = 0.521, K = 2\}$

</table>

On the other hand, Table 2 sets out a situation where the price would explode when only feedback traders are acting on the market. The conditions of Theorem 3 hold for the feedback traders, so, according to Baumann (2015) resp. Theorem 3, their demand causes a bubble in the absence of any other traders. However, if fundamentalists enter the market, price explosion is
prevented, as the demand rates tend to 0 at time \( t = 73 \) in Table 2. Clearly, the conditions of Theorem 8 for feedback traders are not satisfied.

Table 2: The table shows a situation where the price would explode without fundamentalists but is stabilized by them. The investment parameters are the same as for Figure 5 where prices explode. The boxed cells fulfill the conditions required by Theorem 3 \( \{p_0 = 1, M = 1, T = 250, f_t \equiv 1, I_0^C = 0.192, K = 2\} \)

</table>

In summary, even a strong fundamentalistic demand rule, that is a strategy without any restrictions and involving a possibly infinitely large demand, is not able to stabilize the market when a trader using a very simple linear feedback strategy with an adequate initial investment is acting on the market, too. Market failures can happen, prices may explode, and the trading behavior of strong fundamentalists cannot prevent this.

4 Discussion of Effects of Linear Feedback Trading

Our analysis indicates that trend followers with bounded leverage may cause price explosions regardless of fundamentalists’ investment decisions. Specifically, Theorem 8 and its proof analytically show that a fundamentalist’s investment strategy, that is a strategy that pushes prices toward their fundamental values, can be insufficient to dominate linear feedback trading strategies. However, the potential for feedback traders’ to create a bubble appears to be lower (Theorem 8) when fundamentalists are active in the market (cf. Theorem 3). Although the results indicate that fundamentalists have a stabilizing effect (cf. Table 2), this effect is limited up to some threshold value.

Given our results and the fact that financial bubbles are associated with high economic costs, an important question arises: seeing that fundamentalists do not appear to be an adequate market stabilizing force, is there another
type of trader that would be able to stabilize prices in a market-appropriate way and, if so, what would such a trader look like? Generally, our analysis supports the view that intervention measures or at least some kind of incentive system is necessary to stabilize asset markets and prevent financial bubbles. Such measures could, for example, be the direct intervention of some regulatory or supervisory authority, progressive transaction costs, or trading restrictions.
